Software Process versus Design Quality
Tug of War?

Girish Suryanarayana, Tushar Sharma, and Ganesh Samarthyam

“Something smells rotten in the state of our design.” This realization might come despite all good intentions behind choosing and following the “right” process. Don’t underestimate a process’s inadvertent effects on the resulting software design’s quality, as evidenced in two insightful stories from Girish Suryanarayana, Tushar Sharma, and Ganesh Samarthyam that are based on their recently published book on design smells. Enjoy! —Cesare Pautasso and Olaf Zimmermann, department editors

SOFTWARE LIFE-CYCLE PROCESSES provide a structured, disciplined way to guide the development of complex real-world software.1,2 These processes can be primary (acquisition, supply, development, operation, and maintenance), supporting (for example, documentation, configuration management, quality assurance, reviews, audits, or problem resolution), or organizational (management, infrastructure, improvement, and training).3 Our interests lie in software design, so we pose this question: Do software life-cycle processes (henceforth simply called software processes) benefit software design?

The answer is a clear yes! For instance, a software process that recommends periodic architecture and design reviews to ensure the design quality, and supports traceability between the requirements and design elements to ensure the design’s completeness, helps ensure high-quality design.4,5

However, our experience with design smells in real-world projects and interviews with software engineers from various organizations6 have revealed a paradox. Sometimes, a design exhibits smells because a software process (or combination of processes) has inadvertently become a significant hindrance to high design quality, thus negating the benefits the process was meant to deliver. In some cases, a process has actually undermined design quality. In these cases, an approach that aims to address the design smells and improve the design quality can’t merely rely on tactical refactoring of the design artifacts. It also must refactor the process, remove it, or introduce another process.
A key insight from these cases is that software processes and design quality are inextricably intertwined. To highlight this interplay, we examine the following two real-world cases.

A Suboptimal Change Approval Process
In a globally distributed software development project, a central team (Team A) owned the code base. Team A included domain experts who had originally designed the software. The development was off-shored to another team (Team B).

When an external consultant analyzed the code base after the release of the software's first version, he found smells in the design and code. For instance, several classes suffered from the identical-implementation form of the Duplicate Abstraction smell (see the sidebar). Surprisingly, Team B was aware of the extensive code duplication but had made no effort to refactor the design.

The consultant discovered that the lack of refactoring was due to the process the project followed. To prevent unwarranted modifications that could negatively impact the product’s functionality, the project relied on a stringent process to control source code changes. Team A had to review any code change made by Team B before the change could be approved. This review focused on functional correctness (from a domain perspective), not the code's structural quality. This change approval process was long and arduous and required multiple emails and telephone interactions between the teams.

To reduce the time to ratify changes that slowed the development rate, Team B wanted to avoid this process as much as possible. Because refactoring (including refactoring to eliminate code clones) would involve only structural changes to the code without impacting the functionality, it seemed logical to avoid refactoring to avoid the change approval process. So, Team B wasn’t keen to refactor the source code. In this case, the environment viscosity created by the process led to the software’s poor design quality. The consultant shared this finding in his final report and suggested refactoring the change approval process.

The project management could have refactored the change approval process in several ways. For example, they could have incorporated review of code quality into it. Instead, they refactored it to have Team A ratify only new class additions and not every small change that Team B made. The project management be-

---

THREE SOFTWARE DESIGN SMELLS

Here we look in more detail at the three design smells mentioned in the main article. For more on them and other design smells, see Refactoring for Software Design Smells.

DUPLICATE ABSTRACTION
This design smell has two forms. Identical name is when two or more abstractions have identical names. Identical implementation is when two or more abstractions have semantically identical member definitions, but the design hasn’t captured and used those implementations’ common elements.

INSUFFICIENT MODULARIZATION
This smell arises when an abstraction hasn’t been completely decomposed and a further decomposition could reduce its size, implementation complexity, or both. This smell has two forms. Bloated interface is when an abstraction has many members in its public interface. Bloated implementation is when an abstraction has many methods in its implementation or has one or more methods with excessive implementation complexity.

MULTIPATH HIERARCHY
This smell arises when a subtype inherits both directly and indirectly from a supertype, causing unnecessary inheritance paths in the hierarchy. This complicates the hierarchy and increases developers’ cognitive load, thus reducing the hierarchy’s understandability. Furthermore, developers might overlook existing implementations on the redundant paths and try to provide their own implementation for the realized interface. In this process, they could provide a considerably different implementation (or no implementation). Such mistakes can lead to run-time problems. So, this smell can impact reliability.

Reference
lieved this would eliminate the viscosity (by reducing the number of times the change approval process was initiated), which in turn would improve the design quality.

Upon the release of the software’s second version, the consultant again analyzed the design quality. Surprisingly, he found many more instances of the Insufficient Modularization smell (see the sidebar), compared to the first release. For example, one class in the source code had approximately 40,000 LOC, and the weighted methods per class (the sum of the cyclomatic complexities of a class’s methods) exceeded 2,000.

The consultant found that part of the root cause of the many instances of the Insufficient Modularization smell was still the change approval process. Toward the software’s second release, the project management at the off-shore location became concerned about the many bugs (in the order of hundreds) found during testing, which posed a risk for timely delivery. To ensure that the software was released on time, the project management assigned each developer in Team B a target of fixing four bugs every week.

Fearing that they would be considered underperforming if they couldn’t fix four bugs per week, the members of Team B explored ways to avoid the change approval process for new classes that bug fixing might require. One easy way to avoid introducing classes was to insert new code in existing classes. Because of schedule pressures, many developers adopted this workaround, which resulted in many Insufficient Modularization instances.

Because this workaround was convenient and the large classes produced no immediate runtime effects, it evolved into a bad habit during development for the third release. It also explained why Team B didn’t refactor these large classes immediately after the release. Refactoring them would have required introducing smaller classes, which would have required going through the change approval process.

The project management could have addressed this problem in various ways. For instance, it could have refactored existing processes (for example, refactor the change approval process to remove bottlenecks and improve the turnaround time for change review). Or, it could have removed them (for example, remove the bug-target-setting process so that developers don’t bypass change approval). Alternatively, or in combination with the ways we just mentioned, the project management could have introduced a process (for example, introduce a local change approval process to speed up approval).

In this case, for the product’s third release, the project management removed the bug targets. They also adopted a design quality gate process that required each developer to run a set of design analyzers on the portion of code he or she had modified, before checking-in the code. This helped address the problem significantly, and the number of smells drastically decreased during the third release.

An Ineffective Design Communication Process

Industrial software systems often create complex domain objects to fulfill complicated business requirements. The initialization of such objects typically involves a sequence of steps, including preinitialization and postinitialization. These two steps are crucial, and software developers must remember to write an implementation for them. To ensure this,
realize ISupportInitialize and provide the default implementation of preInitialize() and postInitialize() (see Figure 1b).

However, the developer entrusted with implementing NumericGadget was on leave when the rest of the team discussed this new design. By the time he returned, the old design had been refactored and the new design was in place. Unfortunately, no one told him about this design decision.

This situation occurred because the project followed an agile methodology and subscribed to the principle that individuals and interactions are more important than detailed documentation.9 Specifically, the team discussed and communicated design decisions during stand-up meetings. It explicitly documented only the architectural design decisions10 (such as introducing a new layer or changing the middleware being used) in the architecture specification. In this case, the team considered that having GadgetBase directly implement ISupportInitialize wasn’t an architectural decision, so the team didn’t explicitly document this design change.

Because the developer was unaware of the noncritical design decisions, he implemented NumericGadget using the old paradigm. That is, NumericGadget extended GadgetBase and realized ISupportInitialize (see Figure 1c). The resulting design thus suffered from the Multipath Hierarchy design smell (see the sidebar).

In short, this design smell arose because the process used to communicate design decisions and changes to all the team members wasn’t effective. A more potent process aligned with the agile methodology would have employed multiple communication modes to convey design decisions. For example, it would have additionally used emails or lightweight knowledge management systems such as wikis to document all design decisions so that they were always available to the entire team.9

These two cases highlight the process–quality paradox: software processes are designed to bring discipline to software development and intend to help achieve and maintain high-quality software design. However, some software processes (because of how they’re implemented or the project conditions) turn out to be cumbersome or porous, leading to situations that can decrease design quality. Software design quality is a function of the effectiveness of the followed process in a given context. So, such situations require us to introduce, tune, or refactor existing processes to achieve and maintain high design quality. In conclusion, these cases lead to the following insights.

First, all the relevant stakeholders need to recognize the interplay between software processes and design quality.

Second, development teams must periodically evaluate design quality (for instance, by looking for design smells). If the quality is poor, teams must determine whether any software process is the cause.
Finally, if the cause of poor design quality is process-related, teams can address it by refactoring or removing an existing process or introducing a new one, as we mentioned before. Refactoring a process might include identifying and removing the obstacles that directly or indirectly hamper good quality.

Software Engineering for Big Data Systems
Submission deadline: 1 August 2015 • Publication: March/April 2016

This special issue focuses on the software-engineering challenges of building massively scalable, highly available big data systems. Such systems are highly distributed and often comprise multiple architectural styles and open source technologies. Growth in scale and functionality is often unanticipated and explosive, which drives organizations to adopt rapid development and deployment methods to cope with ever-changing requirements, environments, and data types.

Possible submission topics include, but aren’t limited to,
- the engineering of big data systems, including software design and architecture, software development approaches, and management methods;
- architectural adaptation of legacy systems for big data analytics;
- software engineering techniques that ensure accurate results from operational data analysis;
- security and privacy issues in engineering big data applications;
- novel application software architectures to address the CAP theorem’s constraints;
- distributed algorithms and frameworks for scalable data analysis and processing;
- programming-language support for data parallel processing;
- quality assurance for big data systems, including run-time monitoring at scale;
- data management and evolution for big data systems; and
- performance, scalability, and capacity planning and analysis.

Submission Guidelines
Manuscripts must not exceed 4,700 words including figures and tables, which count for 250 words each. Submissions over these limits may be rejected without refereeing. Articles deemed within the theme and scope will be peer-reviewed and subject to editing for magazine style, clarity, organization, and space. Submissions should include the special issue’s name.

Articles should be novel, have a practical orientation, and be written in a style accessible to practitioners. Overly complex, purely research-oriented, or theoretical treatments aren’t appropriate. IEEE Software doesn’t republish material published previously in other venues.
